**TITLE:** Evaluation of Mint Cultivars in the Presence and Absence of *V. dahliae*.

**PERSONNEL:** Leon E. Welty, Professor of Agronomy, MSU, Kalispell, MT  
Louise S. Prestbye, Research Technician, MSU, Kalispell, MT

**OBJECTIVE:** Determine adaptability of existing and experimental peppermint and spearmint cultivars for pest tolerance, oil yield and quality, and stand life with and without Verticillium wilt.

**PROCEDURES:** Peppermint and spearmint cultivars (Tables 1 & 2) were established at the Northwestern Agricultural Research Center at Kalispell, MT in spring of 1994. The experiment was planted at two sites (one to be infected with Verticillium wilt and one to be kept free of the disease) in Creston silt loam soils.

Nuclear plants were obtained from three different sources. Black Mitcham - stem-plug was obtained from Lakes, Ronan, MT. Meristem Black Mitcham, Meristem Native and Scotch spearmint were obtained from Starkels, Ronan, MT. All other entries were provided by MIRC from Dr. Don Robert's breeding program. Nuclear plants were planted on one foot centers. Each plot consisted of four rows spaced 20 inches apart, 20 feet in length. Harvest area for hay yield was 86.7 square feet. The peppermint and spearmint experiments were arranged separately in randomized complete block designs with four replications.

During the first month after planting, plots were kept moist to insure adequate establishment. Thereafter, each nursery was sprinkler irrigated to insure maximum growth. Each experimental site was fertilized with P, K, and S prior to planting. Nitrogen was applied at a total rate of 170 lb/A in three separate applications throughout the growing season. No pesticides were applied to the cultivars in 1994. Weeds were controlled by hand.

Cultivars were evaluated for agronomic characteristics and disease on 8/17, 8/31, and 9/22/94. Dry matter yields were obtained at one site on Sept. 27. Approximately 20 pounds of green hay was air dried and later distilled. Samples were sent to A.M. Todd for quality analyses.

#### **RESULTS AND DISCUSSION:**

Interpretation of 1994 data must be done with caution because cultivars were planted at three different dates (Table 3). Legitimate comparisons can be made among Black and Murray Mitcham cultivars and experimental cultivars obtained from MIRC since they were planted on the same date.

Initial establishment and vigor was superior for Black Mitcham-plug and meristem spearmints because they were the first cultivars established. By August 17, all peppermint cultivars had covered the row except T-84-5, Murray, and M-83-7 (Table 1a). Stolon spread at this time was similar for all cultivars.

By August 31, all cultivars had covered the rows. Stolon spread was greatest for Black Mitcham - plug, Black Mitcham - meristem, and Black Mitcham - stem (Table 1b). Powdery mildew was beginning to appear, particularly for Black Mitcham - meristem.

On September 22, all cultivars had powdery mildew with the Black Mitchams having the greatest incidence of the disease (Table 1c). Also, peppermint rust was evident on the Black Mitchams. Interestingly, Black Mitcham - meristem, which is purported to be more susceptible to rust than stem tip Black Mitcham, had the least rust of all Blacks. This was probably related to stage of mint growth coinciding with rust development, since the meristem Black was the last mint planted.

Meristem spearmints were more vigorous, covered the row earlier and had more stolon spread than stem tip spearmints (Tables 2a,b,c). Whether this was due to planting date or the meristem process cannot be determined. Scotch spearmints had significant levels of powdery mildew on Aug. 31 and were severely infested by Sept. 22. Meristem Scotch had significantly more rust than stem-tip Scotch on Sept. 22.

Black Mitcham stem-tip - plug produced the highest oil yield of all peppermint cultivars (Table 3). Black Mitcham stem tip from MIRC produced the next highest oil yield which was surprising considering the condition of the nuclear plants. Meristem Black produced substantial oil considering it was planted at least two weeks after all other cultivars.

Meristem spearmint produced more oil than stem-tip spearmint regardless of species. Again, no conclusions can be drawn because of the difference in planting date.

Oil analyses showed significant differences in quality components among cultivars (Table 4). Black Mitcham was lower in menthol and higher in menthyl acetate (ester) than the other peppermint cultivars regardless of planting date. Scotch spearmint was higher than Native in total heads, limonene and carvone.

In fall 1994, two rates of *V. dahliae* were planted across all mint cultivars at one site. Cultivar response to this disease will be measured in 1995. The other site will be maintained *Vert* wilt free.

**TITLE:** Meristem 'Black Mitcham' Peppermint Double Cut Study

**PERSONNEL:** Leon E. Welty, Professor of Agronomy, MSU, Kalispell, MT  
Louise S. Prestbye, Research Technician, MSU, Kalispell, MT

**OBJECTIVE:** Determine the effect of double cutting on oil yield, quality, and stand life of meristem Black Mitcham peppermint compared to a traditional single harvest at 10% bloom.

**PROCEDURES:** At the Northwestern Agricultural Research Center at Kalispell, MT in spring of 1994, plots 10' wide by 15' long were delineated within a third year stand of meristem derived Black Mitcham peppermint (root source - Glacier Mint). Four replicates of 12 plots representing 11 double cut harvests and a single cut control (Table 1) were assigned in a randomized complete block design.

Harvest area was approximately 70 square feet. The area was irrigated with 0.6 to 1.6 inches per week, for a total of 18 inches over the season. In the fall of 1993, 20 lbs/a N, 104 lbs/a P<sub>2</sub>O<sub>5</sub> and 120 lbs/a K<sub>2</sub>O were applied. In 1994, 50 lbs/a S and 410 lbs/a N was applied through the sprinkler during the growing season. Sinbar was applied at 0.5 lb/a on 4/12, Poast at 2 pt/a on 4/27 and Basagran at 2 pt/a on 5/3/94. Orthene, at 0.5 lb/a, was sprayed on 8/11 for cutworm control.

Growth stage, height, and lodging were noted on the prescribed harvest dates for each plot and dry matter yields obtained. Approximately 20 pounds of green hay was air dried and later distilled. Samples were sent to A.M. Todd for quality analyses.

## **RESULTS AND DISCUSSION:**

Oil yields (Table 2) increased as the first harvest was delayed until July 19. The breakpoint for significant oil increase occurred on July 12, which was when the meristem Black started to have significant lodging. The single harvest on Aug.1 produced oil yields which would be considered unacceptable to peppermint producers. Interestingly, after July 12 the peppermint continued to get taller and accumulate biomass without a corresponding increase in oil yield.

Plots were harvested again on Sept. 1 (Table 3a). As expected, oil yields were greater for the earlier first harvests. The highest total oil per acre was received from the July 12 + Sept.1 harvests (99.3 lbs/a - Table 4b).

Harvesting on Sept. 27 for the second time resulted in a reduction in oil yield compared to the Sept. 1 harvest (Table 4b). We anticipated that the additional 26 days of growth would increase or at least maintain yields, but this did not occur. We don't think the reduction in oil yield from Sept. 1 to Sept. 27 was the result of weather, because only 4 mild frosts were observed in September. We think the oil yield reduction was due to leaf drop and rot resulting from lodging. The reduction was most severe for the June harvests which had the longest time for regrowth.

Oil analyses showed significant differences in quality components among first harvest dates (Table 5a) which were related to plant maturity. The single harvest control (8/1), which had just started to bloom, was highest in heads, menthol, menthofuran and ester, and lowest in menthone. Oil from the second cuttings was generally higher in the levels of the components shown except menthone (Table 5b), and the 9/27 cutting was higher than the 9/1 cutting (Table 5c). Menthol levels of all the 9/27 treatments were similar regardless of first harvest date. Menthol levels for June and early July harvests were below what oil buyers prefer. It must be noted, however, that early harvest oil from production fields in 1994 was marketed without any price discount. This will, of course, vary with supply and demand. If oil supplies are abundant, discounts on early cut peppermint oil could be a reality.

Double cutting was very successful in 1994. However, we all know that 1994 was a good year for this practice. Growing degree days (GDD) as measured at the NWARC are presented in Tables 6 and 7. GDD were 9% higher in 1994 than the 46-year average. If 1994 was a perfect year for double cutting then 1993 would have been one of the worst. However, even in 1993 we obtained 8 inches of regrowth from our Aug. 1 harvest. The unanswered question concerning double-cutting is the effect on peppermint vigor and stand life. This experiment will be continued so that determination can be made.

**TITLE:** Determine Feasibility of Using Rotational Crops to Reduce Pest Problems in Peppermint

**PERSONNEL:** Leon E. Welty, Professor of Agronomy, MSU, Kalispell, MT  
Louise Prestbye, Research Technician, MSU, Kalispell, MT  
Dr. Don Mathre, Plant Pathologist, MSU, Bozeman, MT  
Dr. Bill Grey, Plant Pathologist, MSU, Bozeman, MT

**PROCEDURES:** Cultures of Verticillium dahliae were isolated from peppermint root samples collected from several fields in the Flathead Valley in February, 1992. Sterile oat kernels were inoculated with spore suspensions from these cultures and incubated until numerous microsclerotia of the fungus were visible on the husks. Greenhouse tests on the pathogenicity of the infested kernels were positive for V. dahliae.

Oat kernels were ground with a coffee grinder and mixed with ground wheat in a 50:50 ratio. On 21 May, 1992, the oat kernel-wheat mixture containing the fungus was seeded at a 2-inch depth at 50 lbs/acre into two fields, one with a fine sandy loam (light) soil and one with a silty clay loam (heavy) soil. Plots were arranged in an RCB design with four replicates for the following treatments:

1. Barley - grain harvested, residue plowed
2. Fallow - hand weeded
3. Vapam fumigant - 50 GPA
4. Sorghum (high HCN), plowed as green manure
5. Marigold, plowed as green manure
6. Winter rapeseed (high glucosinolate), plowed as green manure

On September 5, 1992, the green manure crops were rototilled by treatment so soil and plant debris were not moved from plot to plot.

On May 18, 1993, Black Mitcham meristem foundation roots were hand planted (in one-half of each plot) in four, 17 ft. rows per plot at each site. Planting rate was one 5 gallon bucket of roots per plot. The other half of each plot was strip planted to Humus rapeseed, which was harvested for yield determination on 8/30, returned to the plots and plowed down. Vapam was applied to the barley treatment plots at 100 GPA and to the fallow treatment plots at 200 GPA on 9/23/93.

Meristem Black Mitcham was planted on double green manure plots and fall 1993 Vapam plots (100 and 200 GPA) on 5/24/94. Nitrogen was applied at 100 lbs/a and P<sub>2</sub>O<sub>5</sub> at 50 lbs/a on 5/4/94. Sinbar (1.2 lbs/a), Poast (1.5 pt/a + 2 pt/a Dash) and Basagran (2 pt/a + UAN) were applied

5/6/94. On 6/30/94, Tilt was applied at 10 oz/a for rust control. Additional N was applied at 70 lbs/a on 7/13, and another 40 lbs applied to the 1994 planting on 8/26.

Weed invasion was determined by visual estimate and by comparing the fresh weight of all weeds hand-pulled from each plot on 8/8/94. The percentage of each subplot (1993 and 1994 plantings) exhibiting Vert wilt symptoms was visually estimated on 8/11 and again on 9/20/94.

## **RESULTS:**

At the heavy soil site, Vapam in either 1992 or 1993 suppressed weeds, as did the rapeseed and marigold green manure treatments from 1992 (Table 1). The sorghum green manure plots had the most weeds. Very few weeds were present at the light soil site. This data suggests the use of high glucosinolate rapeseed as a green manure crop may benefit weed control in a peppermint rotation scheme.

Vert wilt symptoms appeared in the second-year mint plantings by mid summer. Symptoms appeared later in the new stands. The only significant differences observable at either site were on the 9/20 observation of the 1994 planting (Table 2). The Vapam treated subplots showed lower infestation than the plots which had not been fumigated. In 1993, mint plants in marigold green manure plots showed slightly less disease than plants in other green manure treatments on the light soil. There was some evidence of continued control in the 1994 planting.

## RESEARCH PROGRESS REPORT FOR 1994

**TITLE: NITROGEN AND IRRIGATION MANAGEMENT FOR PEPPERMINT**

Scheduling and Rate Effects on Tissue Nitrate, Soil N Behavior,  
and Oil Yields

**PERSONNEL: PI:** Dr. Mal Westcott, Professor of Soil Science (Fertility)  
Western Ag Research Center, Montana State University

**Cooperators:** Leon Welty, Professor of Agronomy  
Northwestern Ag Research Center, MSU

Dr. Jon Wraith, Assistant Professor of Soil Science (Physics)  
Department of Plant and Soil Sciences, MSU

**OBJECTIVES:** Our objectives are to improve use efficiency for nitrogen fertilizer and irrigation in peppermint production; to develop guidelines for optimum economic input; and to define management standards for minimum impact on environmental quality.

Our approach is to develop a system of precise nitrogen management based on rapid diagnostic procedures for determination of crop nitrogen status, to determine crop water use and model water behavior and solute transport in the soil profile, and delineate the interaction between these factors.

**PROCEDURES:** A field trial investigating nitrogen fertilization interactions with irrigation scheduling and amounts was conducted on second-year peppermint (Black Mitcham) at the Northwestern Agricultural Research Center, located in Montana's Flathead Valley production area. The experimental design was a randomized complete block (4 replications) with two irrigation schedules as main plots and eleven nitrogen treatments as subplots (8x60 ft). The eleven treatments were:

**Control** (No added N)

120 lb N/ac standard\*  
240 lb N/ac standard  
360 lb N/ac standard  
480 lb N/ac standard  
600 lb N/ac standard

120 lb N/ac single\*\*  
360 lb N/ac single  
600 lb N/ac single

**PRFC\*\*\*** (plant response fertilization based on chlorophyll levels)

**PRFS** (plant response fertilization based on stem nitrate levels)

\*Standard application seeks to mimic the common practice of frequent nitrogen application through irrigation systems. Nitrogen rates were divided into seven equal increments applied weekly commencing June 22 as urea solution by backpack sprayer on plots immediately prior to irrigation.

\*\*Single application was of the total amount as granular urea applied at the beginning of irrigation treatment in June.

\*\*\*Plant response fertilization (PRF) was managed by applying a rate of 90 lbs N/ac as granular urea at the beginning of the irrigation season and basing further applications on the diagno-

sis of deficiencies by comparing SPAD chlorophyll readings or stem sap nitrate levels to well fertilized plots.

These subplots were arrayed perpendicular to a line-source sprinkler system which delivered a gradient of decreasing irrigation amounts as a function of distance from the line. The same amount of water was applied to each irrigation schedule main plot each week: 2 inches at a distance of 20 feet from the line-source adjusted for rainfall. One schedule received the total amount in one weekly application and the other schedule received it in two equal weekly applications. The wettest regime adjacent to the line received 2.5 inches weekly, extending to dryland conditions at the outer margins (50 ft) of the plots.

Tensiometers at depths of 6, 24, and 48 inches and neutron probe access tubes were installed at distances of 5, 20, and 35 feet from the line-source in the 360 lb N/ac treatment of each irrigation scheduling main plot in each replication. Tensiometer readings were taken weekly, prior to irrigation. Suction lysimeters were installed to a depth of four feet at distances of 5, 20, and 35 feet from the line-source in the 0, 360, and 600 lb N/ac treatments of each irrigation schedule and each rep. Soil solution extracts were taken weekly.

A new technique was employed for the detection of nitrate leaching. Access tubes were installed at angles to depths of 6, 24, and 48 inches to allow for insertion of ion exchange resin capsules in contact with the soil. Bromide (a tracer for nitrate) as well as nitrogen fertilizer were applied to the soil surface above these access tubes. The resin capsules were assayed weekly for nitrate and bromide content.

Plant stem and soil samples were taken from selected treatments on a weekly basis. Stem sap nitrate concentration was measured with a laboratory model nitrate-specific electrode. Stem nitrate content on a dry matter basis was measured by KCl extracts from ground material. Soil samples are currently being extracted for nitrate concentration analysis. In addition, the chlorophyll content of plant leaves was measured with the SPAD meter, which gives a digital readout of green wavelength light reflectance.

Yield was determined on August 3 by taking parallel swaths at distances 9, 16, 24, 31, and 39 ft from the line-source in each plot with a small-plot forage harvester. Hay fresh weights were recorded and a subsample was taken for moisture and total plant nitrogen determination. Oil content of the hay was determined from all plots in the 24 ft increment and selected plots in the 9 and 39 ft increments. This was done by distillation of dry hay samples in a small-scale distillation facility.

Soil core samples to 4 ft depth were taken after harvest in selected plots at three irrigation levels. The cores were divided into one-ft increments for extraction and analysis of nitrate concentration.

## RESULTS:

Yield Response to Nitrogen. Under optimum irrigation, oil yields responded to N fertilization rates up to 240 lbs N/ac, with no further significant yield responses as N rates increased beyond that rate (Fig. 1). The slope of the regression equation in Fig. 1 indicates that within the range of oil yield response, it required the addition of 17 lbs N/ac to increase oil yields by one pound/ac. Single applications of urea were as effective as the standard incremental applications of similar rates.

Stem NO<sub>3</sub>, Sap NO<sub>3</sub>, and SPAD Analysis of Crop N Status. All three plant testing methods were sensitive to differences in crop N status and readily reflect N fertility management (Figs. 4a-c). There were differences between the methods in the patterns displayed over the course

of the season.

**Relationship Between Crop N Status and Yield.** There was a very good correlation between midseason (July 7) crop N status and final oil yield (Figs. 2 and 3). Yields increased in a linear fashion with increasing sap  $\text{NO}_3\text{-N}$  levels up to 600 ppm and with increasing stem  $\text{NO}_3\text{-N}$  levels up to 5500 ppm and showed no response to higher levels. The outliers in this analysis are the sap  $\text{NO}_3$  levels in the PRF treatments (Fig. 2). The particular management of these treatments, where we allowed crop N status to decline and then resumed fertilization, obviously effected the relationship between midseason N status and final yield. This illustrates that these temporary deficiencies can be recovered effectively.

**Plant Response Fertilization.** Plant Response Fertilization (PRF) is an approach to precise fertilizer management based on progressive plant diagnosis. The idea is to apply a moderate rate of nitrogen fertilizer to a production field and a heavy rate to a designated reference plot located within the production field. The reference plot and the production field are monitored by some diagnostic procedure on a regular basis throughout the growing season. Additional fertilizer is not applied to the production field until a deficiency is detected by comparison to the reference plot. The goal is high yields with less fertilizer. Such a system obviously requires a rapid diagnostic procedure to detect nitrogen status of the crop, preferably one that can be completed on site.

The PRF treatments included the SPAD chlorophyll meter (measures leaf greenness) and sap  $\text{NO}_3$  analysis as tools for monitoring crop N status. We initially applied 90 lbs N/ac to these plots and then took SPAD leaf readings or sap  $\text{NO}_3$  readings on a weekly basis, using the higher N rate treatments as reference. Figure 5 illustrates how we managed the PRF sap  $\text{NO}_3$  plots. Compared to other treatments, deficiencies in the PRF plots were not detected until week 4 (Fig. 5). We therefore began applying additional N to the PRF plots in week 5, putting on two applications of 60 lb N/ac each to finish out the season (210 lbs N/ac total). The sap  $\text{NO}_3$  readings show the recovery of the plants from this deficiency.

Both PRF treatments (chlorophyll or stem nitrate) resulted in oil yields as high as any N rates of 240 lbs N/ac or greater. The goal of achieving high yields with less fertilizer was attained.

**Irrigation Level and Timing.** As in past years, there were no significant differences between the once-per-week vs. twice-per-week irrigation schedules in terms of yield or soil-plant N relations. This is due to the fact that peppermint rooting depth is much greater than previously supposed. This is illustrated in Fig. 6, where we see crop extraction of soil water at a depth of four feet under relatively dry conditions (35 ft distance from the line source). This reflects what was found in 1992 on first-year peppermint where water was extracted from the two-foot depth (high precipitation in 1993 prevented these measurements). It is therefore not surprising that a once-per-week irrigation schedule is sufficient to maintain adequate water availability for the crop.

Oil yields declined as irrigation rates declined below two inches/week (Fig. 7). Yields in 1994 were not significantly affected by higher rates of irrigation, but efficiency of use obviously declined.

**Leaching.** Breakthrough curves for bromide leaching at the 20 and 35 ft increments are shown for the 6, 24, and 48 inch soil depths in Figs. 8 a-c. These curves show the seasonal progression of leached bromide through the soil profile. This added tracer does not appear at the four foot depth until after harvest, which indicates that it stays within the crop rooting zone over the course of the growing season. These results are similar to those found with the resin-capsule measures of  $\text{NO}_3$  movement through the profile (not shown): movement of  $\text{NO}_3$  from added

sources to the bottom of the crop rooting zone occurs primarily after the growing season. These data will be used for comparison of measured vs. modeled (LEACHM) movement of bromide through the soil profile. We'll present those results at the winter meeting.

PEPPERMINT WILD OAT STUDY - SONSTELLIE FARM 1994

Project Code:94-PWO-SON  
Cooperator :DALE SONSTELIE

Location :DALE SONSTELIE FARM  
By:Bob Stougaard

Summary Comments: Surfactant type had a pronounced effect on wild oat control, with the response being most apparent at the 3 oz rate. Of the surfactants evaluated, MSO was more effective than NIS, and wild oat control with both surfactants was improved with the addition of UAN.

Wild oat control was most complete when applied at the 4 leaf stage of wild oat. Control with the early applications may have been less complete due to low evening temperatures of 37 F preceding application. This may have stressed plants and reduced herbicide uptake. Reduced control with the last application was probably due to the greater weed biomass present relative to the earlier applications.

## PEPPERMINT WILD OAT STUDY - SONSTELLIE FARM 1994

Project Code: 94-PWO-SON  
 Cooperator : DALE SONSTELLIE

Location : DALE SONSTELLIE FARM  
 By: Bob Stougaard

### Site Description

Crop: BABY PEPPERMINT      Variety: BLACK MITCHAM      Planting Date: 5-16-94  
 Planting Method: ROOTS      Rate, Unit: 1/10A , A      Depth, Unit: 3 , "  
 Perennial Age, Unit: 0 , YRS      Row Spacing, Unit: 18 , "  
 Soil Temp., Unit: ,      Soil Moisture:      Emergence Date: 6-5-94

Plot Width/Area, Unit: 10 , FT      Plot Length, Unit: 18.3 , FT      Reps: 3  
 Site Type: SILT CLAYLOAM      Seed Bed Desc.:      Ground Cover: NONE  
 Tillage Type: PACKED      Study Design: RCB  
 Field Preparation/Plot Maintenance: WILD OATS SEEDED WITH RESEARCH SEEDER ON 6-3-94

### Soil Description

Texture: SILTY CLAY LOAM      % OM: 6.0      % Sand: 40      % Silt: 40      % Clay: 20  
 pH: 6.5      CEC:      Soil Name: SWIMS SCL      Fertility Level:

MINT GRASS STUDY

Project Code:94-MNTGRASS

Location: KALISPELL

By: Bob Stougaard

Summary Comments: Herbicide injury was observed with the high rate of Assure II when applied with MSO plus 28% UAN. Similar treatments were used in other studies with no observable mint injury. The injury observed in this study was most likely due to the surfactants redissolving herbicide residues that were in the spray boom and hoses. This reconfirms the importance of cleaning spray equipment when going from crop to crop.

Excellent wild oat control was obtained with all herbicide treatments. There were no differences between herbicides, rates or surfactant types. These results suggest that wild oat is easily controlled and that lower herbicides rates should be evaluated in future studies. However the high level of control achieved might be due to the low populations present in the study. Treatment differences might be more apparent under heavier weed pressure.

1994-95 LIVING MULCH STUDY IN PEPPERMINT

Project Code:95-LMS-R5  
Cooperator :MAL WESTCOTT

Location :KALISPELL, MT  
By:Bob Stougaard

Summary Comments: The purpose of this study was to evaluate eight different crops for potential use as living mulch crops for peppermint production. Crops were seeded at either two weeks prior to mint harvest or directly after mint harvest. The first seeding was broadcast by hand to simulate an aerial application while the second planting used a conventional disk drill.

The post-harvest direct seedings produced the best stands. Aerial seedings did not establish well, possibly due to rodent or insect predation. Of the crops evaluated, winter and spring rye produced the most growth with dry weight biomass in excess of 2 and 1 tons per acre respectively. Winter and spring rape produced the least amount of growth, most likely due to competition from the mint crop.

### MINT PGR STUDY - PLANT GROWTH REGULATOR

Project Code:94-MINTPGR  
By:Bob Stougaard

Location :KALISPELL

Summary Comments: The purpose of this study was to determine if plant growth regulators might have a yield enhancing effect on meristem derived peppermint. For both PGR's, the earliest applications produced the most dramatic results. Ethryl had the most obvious effect on mint growth, to the point where the response was almost herbicidal. Initial injury was severe with the earliest applications, but most symptoms diminished by harvest. Early applications of Ethryl resulted in shorter plants, a greater number of leaves retained (base/height ratio), more branching, and a greater number of leaves. However, the initial injury resulted in reduced dry weight and oil yields. Applications of PIX did not result in any morphological differences. However, mint dry weight and oil yields were slightly greater compared to the check.
